

## Forklift Differentials

Forklift Differential - A mechanical tool which can transmit rotation and torque via three shafts is called a differential. Every now and then but not at all times the differential would employ gears and will function in two ways: in vehicles, it receives one input and provides two outputs. The other way a differential functions is to combine two inputs to generate an output that is the sum, average or difference of the inputs. In wheeled vehicles, the differential enables each of the tires to rotate at various speeds while providing equal torque to each of them.

The differential is intended to drive the wheels with equivalent torque while likewise allowing them to rotate at different speeds. When traveling round corners, the wheels of the cars would rotate at different speeds. Certain vehicles such as karts work without a differential and use an axle as an alternative. When these vehicles are turning corners, both driving wheels are forced to rotate at the same speed, usually on a common axle which is powered by a simple chain-drive mechanism. The inner wheel must travel a shorter distance compared to the outer wheel when cornering. Without using a differential, the outcome is the outer wheel dragging and or the inner wheel spinning. This puts strain on drive train, causing unpredictable handling, difficult driving and deterioration to the roads and tires.

The amount of traction required so as to move the automobile at any given moment is dependent on the load at that moment. How much friction or drag there is, the car's momentum, the gradient of the road and how heavy the automobile is are all contributing elements. One of the less desirable side effects of a traditional differential is that it could reduce traction under less than ideal situation.

The torque supplied to each wheel is a product of the transmission, drive axles and engine applying a twisting force against the resistance of the traction at that particular wheel. The drive train can usually provide as much torque as required except if the load is exceptionally high. The limiting element is commonly the traction under each wheel. Traction can be interpreted as the amount of torque which could be produced between the road surface and the tire, before the wheel begins to slip. The car would be propelled in the intended direction if the torque applied to the drive wheels does not go over the threshold of traction. If the torque applied to every wheel does exceed the traction limit then the wheels would spin continuously.
